CS 229 Machine Learning
Question: Reinforcement Learning - The Inverted Pendulum
"""
from __future__ import division, print_function
from env import CartPole, Physics
import matplotlib.pyplot as plt
import numpy as np
from scipy.signal import lfilter

"""
Parts of the code (cart and pole dynamics, and the state
discretization) are inspired from code available at the RL repository
http://www-anw.cs.umass.edu/rlr/domains.html

Briefly, the cart-pole system is described in `cart_pole.py`. The main
simulation loop in this file calls the `simulate()` function for
simulating the pole dynamics, `get_state()` for discretizing the
otherwise continuous state space in discrete states, and `show_cart()`
for display.

Some useful parameters are listed below:

`NUM_STATES`: Number of states in the discretized state space
You must assume that states are numbered 0 through `NUM_STATES` - 1. The
state numbered `NUM_STATES` - 1 (the last one) is a special state that
marks the state when the pole has been judged to have fallen (or when
the cart is out of bounds). However, you should NOT treat this state
any differently in your code. Any distinctions you need to make between
states should come automatically from your learning algorithm.

After each simulation cycle, you are supposed to update the transition
counts and rewards observed. However, you should not change either
your value function or the transition probability matrix at each
cycle.

Whenever the pole falls, a section of your code below will be
executed. At this point, you must use the transition counts and reward
observations that you have gathered to generate a new model for the MDP
(i.e. transition probabilities and state rewards). After that, you
must use value iteration to get the optimal value function for this MDP
model.

`TOLERANCE`: Controls the convergence criteria for each value iteration
run. In value iteration, you can assume convergence when the maximum
absolute change in the value function at any state in an iteration
becomes lower than `TOLERANCE.

You need to write code that chooses the best action according
to your current value function, and the current model of the MDP. The
action must be either 0 or 1 (corresponding to possible directions of
pushing the cart)

Finally, we assume that the simulation has converged when
`NO_LEARNING_THRESHOLD` consecutive value function computations all
converged within one value function iteration. Intuitively, it seems
like there will be little learning after this, so we end the simulation
here, and say the overall algorithm has converged.

Learning curves can be generated by calling a code snippet at the end
(it assumes that the learning was just executed, and the array
`time_steps_to_failure` that records the time for which the pole was
balanced before each failure is in memory). `num_failures` is a variable
that stores the number of failures (pole drops / cart out of bounds)
till now.

Other parameters in the code are described below:

`GAMMA`: Discount factor to be used

The following parameters control the simulation display; you dont
```

```
really need to know about them:

`pause_time`: Controls the pause between successive frames of the
display. Higher values make your simulation slower.
`min_trial_length_to_start_display`: Allows you to start the display only
after the pole has been successfully balanced for at least this many
trials. Setting this to zero starts the display immediately. Choosing a
reasonably high value (around 100) can allow you to rush through the
initial learning quickly, and start the display only after the
performance is reasonable.
"""

def initialize_mdp_data(num_states):
    """
    Return a variable that contains all the parameters/state you need for your MDP.
    Feel free to use whatever data type is most convenient for you (custom classes, tuples, dicts, etc)

    Assume that no transitions or rewards have been observed.
    Initialize the value function array to small random values (0 to 0.10, say).
    Initialize the transition probabilities uniformly (ie, probability of
        transitioning for state x to state y using action a is exactly
        1/num_states).
    Initialize all state rewards to zero.

    Args:
        num_states: The number of states

    Returns: The initial MDP parameters
    """
    transition_counts = np.zeros((num_states, num_states, 2))
